Modern C++ Programming

3. Basic Concepts II

Federico Busato

University of Verona, Dept. of Computer Science 2018, v1.0

Agenda

- Memory Management: Heap and Stack
 - Heap allocation and memory leak
 - Stack memory
 - Stack 2D allocation
 - Initialization
 - Data/Bss memory segment
- **Storage Class Specifiers Pointers and References**
 - Pointers
 - Void Pointer
 - Address-of Operator
 - Pointer Arithmetic
 - Reference
- sizeof Operator

- Other Keywords
 - const, constexpr
 - volatile
 - using, decltype
- Explicit Type Conversion
- **Declaration and Definition**
- Functions
 - Call-by-value/pointer/reference
 - inline - Default parameters
 - Overloading
- Unions and Bitfields
- Preprocessing
 - Macro
 - Pragma 1/58

Memory Management:

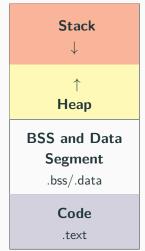

Heap and Stack

higher memory

addresses

0x00FFFFFF

stack memory int data[10]

dynamic memory new int[10]

Static/Global int data[10]
data (global scope)

Dynamic allocation on **heap** in C:

The C++ operator new is applied to allocate a variable/object/etc. in heap memory:

Note. For an array of objects:

- delete/delete[] recursively invoke destructor (see next lectures)
- delete/delete[] applied to nullptr has no effect (safe)

Definition (Memory Leak)

Dynamically allocated entity in heap memory is no longer used by the program, but still maintained overall its execution

An object is stored in memory but cannot be accessed by the running code

Problems:

- Illegal memory accesses
- Undefined values
- Additional memory consumption

Fundamental rules:

- Each object allocated with new must be deallocated with delete
- Each object allocated with new[] must be deallocated with delete[]

Common errors:

Pointer loss and wild pointer:

Double delete:

```
int* array = new int[10];
delete[] array; // ok -> array: dangling pointer
delete[] array; // double free or corruption!!
// program aborted
```

Unless it is allocated in heap memory (i.e. new), then it is either in stack memory or CPU registers

Important:

Every object which resides in the stack is not valid outside the current scope!!

```
int* wrongFunction() {
    int A[3] = {1, 2, 3};
    return A;
}

int main() {
    int* ptr = wrongFunction();
    cout << ptr[0]; // Illegal memory access!!
}</pre>
```

Important:

The organization of stack memory enables much higher performance. On the other hand, this memory space is limited!!

It is $\approx 8MB$ on linux by default.

sizeof and memory allocation:

```
int A[10];
int* B = new int[10];
cout << sizeof(A); // print sizeof(int) * 10 = 40
cout << sizeof(B); // print sizeof(int*) = 8 (64-bit)</pre>
```

Easy on stack:

```
int A[3][4];
```

Dynamic Memory 2D allocation/free:

```
int* A = new int*[3];
for (int i = 0; i < 3; i++)
    A[i] = new int[4];

for (int i = 0; i < 3; i++)
    delete[] A[i];
delete[] A;</pre>
```

Dynamic memory 2D allocation/free C++11:

Memory Management (Stack Array Initialization)

One dimension:

```
int A[3] = {1, 2, 3}; // explicit size
int B[] = {1, 2, 3}; // implicit size
char C[] = "abcd"; // implicit size
int C[3] = {1, 2}; // C[2] has undefined value
int D[4] = {0}; // all values of D are initialized to 0
int E[3] = {}; // all values of E are initialized to 0 (C++11)
```

Two dimensions:

```
int F[][] = ...; // compile error
int G[2][] = ...; // compile error
int G[][2] = { {1,2}, {3,4}, {5,6} }; // ok
int H[2][2] = { 1, 2, 3, 4 }; // ok
```

Memory Management (Data and BSS Segment)

```
int data[] = {1, 2, 3, 4};  // data segment memory
int big_data[1000000] = {};  // bss segment memory (zero-initialized)
int main() {
   int A[] = {1, 2, 3};  // stack memory
}
```

Data/Bss (Block Started by Symbol) are larger than stack memory (max $\approx 1 \text{GB}$ in general) but slower

Default Initialization

Default Initialization

Rules:

- An object with dynamic (heap) storage duration has indeterminate value
- An object whose initializer is an empty set of parentheses is zero or default initialized
- Objects with static or thread storage duration are zero or default initialized

Initialization

// int d3();

```
int a1;
                  // indeterminate
int* a2 = new int;  // indeterminate
int* a3 = new int(); // indeterminate
int* a4 = new int(4); // allocate a single value equal to 4!!
int* b1 = new int[4]();  // allocate 4 elements zero-initiliazed
int* b2 = new int[4]{};  // indeterminate
int* b3 = new int[4]{1, 2}; // set first, second, indeterminate
                       // other values
int c1(4);
        // c1 = 4;
int c2 = int();  // zero-initiliazed
int c3(0); // zero-initiliazed
int c4 { 0 };  // zero-initiliazed
```

static int d1; // zero-initiliazed
thread_local int d2; // zero-initiliazed

// d3 is a function

Pointers and References

Pointers and Pointer Dereferencing

Definition (Pointer)

A pointer is a value referring to a location in memory

Definition (Pointer Dereferencing)

Pointer dereferencing means obtaining the value stored in at the location refereed to the pointer

Common errors:

```
int *ptr1, ptr2; // one pointer and one integer!!
int *ptr1, *ptr2; // ok two pointers
```

void Pointer (Generic Pointer)

Instead of declaring different types of pointer variable it is possible to declare single pointer variable which can act as any pointer types

- A void* can be assigned to another void*
- void* can be compared for equality and inequality
- A void* can be explicitly converted to another type.
- Other operations would be unsafe because the compiler cannot know what kind of object is really pointed to. Consequently, other operations result in compile-time errors

```
cout << (sizeof(void*) == sizeof(int*)); // print true

int array[] = { 2, 3, 4 };
void* ptr = array;
cout << *array; // print 2
cout << *ptr; // compile error
cout << *((int*) ptr); // print 2
void* ptr2 = ptr + 2; // compile error</pre>
```

Address-of operator &

The address-of operator (&) returns the address of the variable

```
int a = 3;
int* b = &a; // address-of operator,
             // 'b' is equal to the address of 'a'
a++:
cout << *b; // print 4;
int array[4]; // &array is a pointer to a array of size 4
int size1 = (&array)[1] - array;
int size2 = *(&array + 1) - array;
cout << size1; // print 4</pre>
cout << size2; // print 4</pre>
```

To not confuse with Reference syntax: T& var = ...

$1+1 \neq 2$: Pointer Arithmetic

Pointer syntax:

```
ptr[i] is equal to *(ptr + i)
```

Pointer arithmetic rule:

```
address(ptr + i) = address(ptr) + (sizeof(T) * i)
```

where \mathtt{T} is the type of elements pointed by \mathtt{ptr}

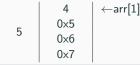

Example:

```
char arr[3] = "abc"
value address
```

'a'	0×0	\leftarrow arr[0]
'b'	0×1	\leftarrow arr[1]
'c'	0×2	\leftarrow arr[2]

int arr[3] =
$$\{4,5,6\}$$

	value	address	
	4	0×0	\leftarrow arr[0]
		0×1	
		0x2	
ı		0x3	

Reference

Definition (Reference)

A variable **reference** is an **alias**, namely another name for an already existing variable. Both variable and variable reference can be applied to refer the value of the variable

References are safer then pointers:

- References <u>cannot have NULL</u> value. You must always be able to assume that a reference is connected to a legitimate piece of storage.
- References <u>cannot be changed</u>. Once a reference is initialized to an object, it cannot be changed to refer to another object.
 (Pointers can be pointed to another object at any time)
- References must be <u>initialized</u> when it is created.
 (Pointers can be initialized at any time)
- A pointer has its own memory address and size on the stack, reference shares the same memory address (with the original variable) but also takes up some space on the stack.

17/58

Reference (Examples)

Reference syntax: T& var = ...

```
//int& d; // reference. compile error!! no initilization
int c = 2;
int& e = c; // reference. ok valid initialization
e++; // increment `e'
cout << c; // print 3</pre>
```

References (Function Arguments)

Reference vs. pointer arguments:

```
void f(int* value) {} // value may be a nullptr
void g(int& value) {} // value is never a nullptr

int a = 3;
f(&a); // ok
g(a); // ok
//g(3); // compile error "3" is not a reference of something
```

References can be use to indicate fixed size arrays:

```
f(int (&array)[3]) {} // accepts only arrays of size 3
int A[3], B[4];
int* C = A;

f(A); // ok
f(B); // compile error!! B has size 4
f(C); // compile error!! C is a pointer
```

19/58

References (Arrays)

Reference:

[1] www3.ntu.edu.sg/home/ehchua/programming/cpp/cp4_PointerReference.html

References and struct

- The dot (.) operator is applied to local objects and references
- The arrow operator (->) is used with a pointer to an object

```
struct A {
   int x = 3;
};
A obj;
A* p = \&obj; // pointer
p->x; // arrow syntax
A& ref = obj; // reference
std::cout << obj.x; // dot syntax</pre>
std::cout << ref.x; // dot syntax</pre>
```

sizeof Operator

The **sizeof** is a compile-time operator that determines the size, in bytes, of a variable or data type

- sizeof returns a value of type size_t
- sizeof (incomplete type) produces compile error
- sizeof (bitfield) produces compile error
- sizeof (anything) never returns 0 except for array of size 0
- sizeof(char) always returns 1
- When applied to structures it also takes into account padding
- When applied to a reference, the result is the size of the referenced type

```
sizeof(int); // 4
sizeof(int*); // 8 in a 64-bit OS
sizeof(void*) // 8 in a 64-bit OS
sizeof(size_t) // 8 in a 64-bit OS
char a;
char& b = a;
sizeof(&a); // 8 in a 64-bit OS (pointer)
sizeof(b); // 1 sizeof(char)
struct A {};
sizeof(A); // 1 : sizeof never return 0
A array1[10];
sizeof(array1); // 1 : array of empty structures
int array2[0];
sizeof(array2); // 0
```

```
struct B {
   int x;
   char y;
};
struct C : B { // C extends B
   short z;
};
sizeof(B); // 8 : 4 + 1 (+ 3) (padding)
sizeof(C); // 12 : sizeof(B) + 2 (+ 2) (padding)
int array[4]
sizeof(array) // 16: 4 elements of 4 bytes
sizeof(array) / sizeof(int); //4 elements
```

Other C++ Keywords

Definition (const keyword)

It indicates objects never changing value after their initialization (they must be initialized when declared)

Evaluated at compile-time

```
int size = 3;
int A[size] = {1, 2, 3}; // Technically possible.
                        // But NOT approved by the C++ standard.
const int SIZE = 3;
// SIZE = 4;  // compile error!!
int B[SIZE] = \{1, 2, 3\}; // ok
const int size2 = size;
int B[size2] = {1, 2, 3}; // BAD programming!! size is not const
// (some compilers allow variable size stack array -> dangerous!!)
```

Constness rules:

- int* → const int*
- const int* *→* int*

- int* pointer to int
 - The value of the pointer can be modified
 - The elements refereed by the pointer can be modified
- const int* pointer to const int. Read as (const int)*
 - The value of the pointer can be modified
 - The elements refereed by the pointer cannot be modified
- int *const const pointer to int
 - The value of the pointer cannot be modified
 - The elements refereed by the pointer can be modified
- const int *const const pointer to const int
 - The value of the pointer <u>cannot</u> be modified
 - The elements refereed by the pointer cannot be modified

Note: const int * is equal to int const*

Tip: pointer types should be read from right to left

constexpr keyword

Definition (constexpr)

C++11 guarantees compile-time evaluation of an expression as long as **all** its arguments are constant

- const guarantees the value of a variable to be fixed overall the execution of the program
- constexpr tells the compiler that the expression results is at compiletime. constexpr value implies const for variables
- C++11: constexpr must contain exactly one return statement and it must not contain loops or switch
- C++14: constexpr has no restrictions

```
constexpr int square(int value) {
    return value * value;
}
const int v1 = square(3); // compile-time evaluation
int a = 3;
const int v2 = square(a); // run-time evaluation
```

volatile Keyword

Definition (volatile)

Volatile is a hint to the implementation to <u>avoid aggressive</u> <u>optimization</u> involving the object because the value of the object might be changed by means undetectable by an implementation

- Using volatile on a variable shared between threads/processes can change the semantics of the program
- Volatile reads/writes can still be reordered with respect to non-volatile ones

Type Alias Keyword (using and decltype)

■ In C++11, the using keyword has the same semantics of typedef specifier (alias-declaration), but with better syntax

```
typedef int distance_t; // equal to:
using distance_t = int;
```

■ In C++11, decltype captures the type of an object or an expression

Explicit Type Conversion

Old style cast (type) value

C++11 cast:

- static_cast does compile-time, not run-time checking of the types involved. In many situations, this can make it the safest type of cast, as it provides the least room for accidental/unsafe conversions between various types.
- reinterpret_cast
 reinterpret_cast<T*>(v) equal to (T*) v
 reinterpret_cast<T&>(v) equal to *((T*) &v)
- const_cast may be used to cast away (remove) constness or volatility.

32/58

Static cast vs. old style cast:

Const cast:

```
const int a = 5;
const_cast<int>(a) = 3; // ok
```

Reinterpret cast: (bit-level conversion)

Narrowing Conversion

C++11 provides protection against **narrowing**, i.e. it against assigning a numeric value to a numeric type not capable of holding that value

Declaration and

Definition

Declaration/Definition

Definition (declaration/prototype)

A **declaration** (or prototype) of an entity is an identifier describing its type

A declaration is what the compiler and the linker needs to accept references to that identifier

Definition (definition/implementation)

An entity **definition** is the <u>implementation</u> of a declaration

Declaration/Definition (incomplete type)

A declaration without a concrete implementation is an $\underline{\text{incomplete}}$ $\underline{\text{type}}$

C++ Entities (class, functions, etc.) can be declared $\underline{\text{multiple}}$ times (also with the same signature)

```
struct A; // declaration 1
struct A; // declaration 2 (ok)
struct B { // declaration and definition
   int b;
// A x; // incomplete type
struct A { // definition
   char c;
```

Functions

Definition (Signature)

Type signature defines the inputs and outputs for a function. A type signature includes the <u>number</u> of arguments, the <u>types</u> of arguments and the <u>order</u> of the arguments contained by a function

Definition (Function Parameter [formal])

A parameter is the variable which is part of the <u>method's</u> signature

Definition (Function Argument [actual])

An argument is the actual value (instance) of the variable that gets passed to the function

```
int f(int a, char* b); // function declaration
                       // signature: (int, char*)
                       // parameters: int a, char* b
int f(int a, char*) { // function definition
                      // b can be omitted if not used
// char f(int a, char* b); // error: same signature
// int f(const int a, char* b); // invalid declaration!
                               // const int == int
int f(int a, const char* b); // ok
int main() {
   f(3, "abc"); // function arguments: 3, "abc"
                 // error: "f" call f(int, const char*)
                 // which is not defined
```

Call-by-Value

Definition (Call-by-value)

Values are copies and assigned to input arguments of the method

Advantages:

 Changes made to the parameter inside the function have no effect on the argument

Disadvantages:

 Performance penalty if the copied arguments are large (e.g. a structure with a large array)

When to use:

Small objects that do not need to be change

When not to use:

- Arrays: arrays decay into pointers, when passed to a function
- Large objects

Call-by-Pointer

Definition (Call-by-pointer)

The addresses of variables are copies and assigned to input arguments of the method

Inside the function, the address is used to access the actual argument used in the call

Advantages:

- Allows a function to change the value of the argument
- Copy of the argument is not made (fast)

Disadvantages:

- The argument may be null
- Dereferencing a pointer is slower than accessing a value directly

When to use:

• When passing built-in arrays (use const if read-only)

When not to use:

Small objects

Call-by-Reference

Definition (Call-by-reference)

The reference of variables are copies and assigned to input arguments of the method

Advantages:

- Allows a function to change the value of the argument
- Copy of the argument is not made (fast)
- References must be initialized (no null pointer)
- Avoid implicit conversion

When to use:

Structs or Classes (use const if read-only)

Examples

```
struct MyStruct {
   int field;
};
void f1(int a);  // call by value
void f2(int& a);  // call by reference
void f3(const int& a); // call by const reference
void f4(MyStruct& a); // requires a.field to access
void f5(int* a);  // call by pointer
void f6(const int* a); // call by const pointer
void f7(MyStruct* a); // requires a->field to access
char c = 'a':
f1(a); // ok, pass-by-value
// f2(a); // compile error!! pass-by-reference
```

inline Function Declaration

Definition (inline)

inline specifier is a hint for the compiler. The code of the function can be copied where it is called (inlining)

```
inline void f(int a);
```

- It is just a hint. The compiler can ignore the hint (inline increases the compiler heuristic threshold)
- The compiled code is larger because the inline function is expanded in-place for every function call

GCC/Clang extensions allow to force inline functions:

```
inline __attribute__((always_inline)) void f(int a);
```

Function Default Parameters

Definition (Default/Optional parameter)

A **default parameter** is a function parameter that has a default value provided to it.

If the user does not supply a value for this parameter, the default value will be used. If the user does supply a value for the default parameter, the user-supplied value is used instead of the default value

- All default parameters must be the rightmost parameters
- Default parameters can only be declared once
- Default parameters can improve compile time because they avoid defining other overloaded functions

Function Overloading (Ambiguous Matches)

An **overloaded declaration** is a declaration with the same name as a previously declared identifier (in the same scope), except that both declarations have <u>different arguments</u> and <u>different definition</u> (implementation)

Overload resolution rules:

- An exact match
- A promotion (e.g. char to int)
- A standard type conversion (e.g. between float and int)
- A constructor or user-defined type conversion

```
void f(int a);
void f(float value);
f(0);  // ok
f('a');  // ambiguous matches, compile error
f(2.3f); // ok
void g(int a);

void h(int a);
void h(int a, int b = 0);
h(3);  // ambiguous matches, compile error
```

Functor (Function as Argument)

Definition (Functor)

Functors, or **function object**, are objects that can be treated as parameters

```
Function type:
<return_type>(*[function_name])(<arg_type1>, <arg_type2>, ...)
int eval(int a, int b, int (*f)(int, int)) {
    return f(a, b);
int add(int a, int b) { //type: int (*)(int, int)
    return a + b;
int sub(int a, int b) {
    return a - b;
cout << eval(4, 3, add); // print 7
cout << eval(4, 3, sub); // print 1
```

45/58

Union and Bitfield

Union

Definition (Union)

A **unions** is a special data type that allows to store different data types in the same memory location

- The union is only as big as necessary to hold its largest data member
- The union is a kind of "overlapping" storage

```
union A {
    int x;
    char y;
}; // sizeof(A): 4

A a;
a.x = 1023; // bits: 00..01111111111
a.y = 0; // bits: 00..01100000000
std::cout << a.x; // print 512 + 256 = 768</pre>
```

Definition (Bitfield)

A bitfield is variable of a structure with a predefined bit width. A bitfield can hold bits instead byte

```
struct S1 {
    int b1 : 10; // range [0, 1023]
    int b2 : 10; // range [0, 1023]
   int b3 : 8; // range [0, 255]
};
struct S2 {
   int b1 : 10;
    int : 0; // force start at bit 32
   int b2 : 10;
};
```

Preprocessing

Preprocessor macros are evil:

Do not use macro expansion!!

...or use as little as possible

- Macros can't be debugged
- Macro expansions can have strange side effects
- Macros have no namespace or scope

Preprocessor Macros:

- #if <condition>, #elif <condition>, #else, #endif
- #if defined(...) equal to #ifdef ...
- #if !defined(...) equal to #ifndef ...
- #define <macro> multi lines \
- #undef <macro> (every macro should be undefined for safety reasons)

Commonly useful macros:

- __LINE__ Integer value representing the current line in the source code file being compiled
- __FILE__ A string literal containing the presumed name of the source file being compiled
- __DATE__ A string literal in the form "MMM DD YYYY"
 containing the date in which the compilation process began
- __TIME__ A string literal in the form "hh:mm:ss" containing the time at which the compilation process began

- Select code depending on the C/C++ version
 - #if defined(__cplusplus) C++ code
 - #if __cplusplus == 199711L ISO C++ 1998/2003
 - #if __cplusplus == 201103L ISO C++ 2011
- Select code depending on the compiler
 - #if defined($_$ GNUG $_$) The compiler is gcc/g++
 - #if defined(__clang__) The compiler is clang/clang++
- Select code depending on the operation system or environment
 - #if defined(_WIN64) OS is Windows 64-bit
 - #if defined(__linux__) OS is Linux
 - #if defined(__APPLE__) OS is Mac OS
 - #if defined(_MINGW32__) OS is MinGW 32-bit
 - ...and many others

Do not define macro in header file and before includes!!

Example:

```
#include <iostream>
#define value // very dangerous!!
# include <big_lib>
using namespace std;
int main() {
    cout << f(4); // should print 7, but it prints always 3
big_lib.hpp:
int f(int value) { // 'value' disapear
    return value + 3;
}
```

Use parenthesis in macro definition!!

Example:

```
#include <iostream>
using namespace std;
#define SUB1(a, b) a - b // wrong
#define SUB2(a, b) (a - b) // wrong
#define SUB3(a, b) ((a) - (b)) // correct
int main() {
   cout << (5 * SUB1(2, 1)); // print 9 not 5!!
   cout << SUB2(3+3, 2+2); // print 6 not 2!!
   cout << SUB3(3+3, 2+2); // print 2
```

Macro make hard to find compile errors!!

Example:

```
1: #include <iostream>
2: using namespace std;
3:
4: #define F(a) {
5: ...
6: ...
7: return v;
8:
9: int main() {
10: F(3); // compile error at line 5!!
11: }
```

In which line is the error??!

In C++11, a **variadic macro** is a special macro accepting a varying number of arguments (separated by comma)

Each occurrence of the special identifier __VA_ARGS__ in the macro replacement list is replaced by the passed arguments

Example:

```
#define PRINT3(...) \
printf("list: %d %d %d\n", __VA_ARGS__);

#define PRINT4(...) \
printf("list: %d %d %d %d\n", __VA_ARGS__);

PRINT3(1, 2, 3)
PRINT4(1, 2, 3, 4)
```

When macros are necessary:

- Conditional compiling: different architectures, compiler features, etc.
- Mixing different languages: code generation (example: asm assembly)
- Complex name replacing: see template programming

Otherwise, prefer const and constexpr, specially for constant values and functions

```
#define SIZE 3 // replaced with
const int SIZE = 3;

#define SUB(a, b) ((a) - (b)) // replaced with
constexpr int sub(int a, int b) {
   return a - b;
}
```

Most important pragmas:

#pragma once In C++11, it indicates that a (header) file is only to be parsed once, even if it is (directly or indirectly) included multiple times in the same source file.

It is an alternative of the standard include guard:

```
#ifndef FILENAME_H
#define FILENAME_H
...code...
#endif /* FILENAME_H */
```

- #pragma unroll Applied immediately before a for loop, it replicates his body to eliminates branches. Unrolling enables aggressive instruction scheduling (supported by Intel/Ibm/Clang compilers).
- #pragma message "text" Display informational messages at compile time. (every time this instruction is compiled).

Pragma(<command>) (C++11)
It is an operator (like sizeof), and can be embedded in a
macro (ex. #define)

```
#define MY_LOOP \
_Pragma(unroll) \
for(i=0;i<10;i++) \
cout<<"c";
```

#error "text" The directive emits a user-specified error message at compile time when the compiler parse the related instruction.

Find the size offset of a field inside a structure:

```
#define FIELD_OFFSET(structure, field)
reinterpret_cast<size_t>(
    &((reinterpret_cast<structure*>(0))->field) )
```

Get the size of an arbitrary type without using sizeof

```
struct A {
    int a;
    float b;
};

std::cout << FIELD_OFFSET(A, b); // print 4
int size;

MY_SIZE(A, size); // size = 8</pre>
58/58
```
